Abstract. The problem of resolving virtual method and interface calls in object-oriented languages has been a long standing challenge to the program analysis community. The complexities are due to various reasons, such as increased levels of class inheritance and polymorphism in large programs. In this paper, we propose a new approach called type flow analysis that represent propagation of type information between program variables by a group of relations without the help of a heap abstraction. We prove that regarding the precision on reachability of class information to a variable, our method produces results equivalent to that one can derive from a points-to analysis. Moreover, we implement a static type analysis tool for our approach. To evaluate our method, we use instrumentation technique to implement a dynamic profiling type recorder. The experimental results show that our approach is more practical in both efficiency and accuracy.

Keywords: Type Analysis; Static Analysis; Method Resolving; Call Graph

1. Introduction

For object-oriented programming languages, virtual methods (or functions) are those declared in a base class but are meant to be overridden in different child classes. Statically determine a set of methods that may be invoked at a call site is important to program optimization, from results of which a subsequent optimization may reduce the cost of virtual function calls or perform method inlining if target method forms a singleton set, and one may also remove methods that are never called by any call sites, or produce a call graph which can be useful in other optimization processes.

Efficient solutions, such as Class Hierarchy Analysis (CHA) [DGC95, Fer95], Rapid Type Analysis (RTA) [BS96] and Variable Type Analysis (VTA) [SHR⁺00], conservatively assign each variable a set of class definitions, with relatively low precision. Alternatively, with the help of an abstract heap, one may take advantage of points-to analysis [And94] to compute a set of object abstractions that a variable may refer to, and resolve the receiver classes in order to find associated methods at call sites.

The algorithms used by CHA, RTA and VTA are conservative, which aim to provide an efficient way to resolve calling edges, and which usually take linear-time in the size of a program, by focusing on the types that are collected at the receiver of a call site. For instance, let x be a variable of declared class A , then at a

Fig. 3. Points-to results on the example

call site $x.m()$, CHA will draw a call edge from this call site to method $m()$ of class A and every definition $m()$ of a class that extends A . In case class A does not define $m()$, a call edge to an ancestor class that defines $m()$ will also be included. For a variable x of declared interface I , CHA will draw a call edge from this call site to every method of name $m()$ defined in class X that implements I . We write $CHA(x, m)$ for the set of methods that are connected from call site $x.m()$ as resolved by Class Hierarchy Analysis (CHA). Rapid Type Analysis (RTA) is an improvement from CHA which resolves call site $x.m()$ to $CHA(x, m) \cap inst(P)$, where $inst(P)$ stands for the set of methods of classes that are instantiated in the program.

Variable Type Analysis (VTA) is a further improvement. VTA defines a node for each variable, method, method parameter and field. Class names are treated as values and propagation of such values between variables work in the way of value flow. As shown in Figure 2 (example code in figure 1), the statements on line 1 – 4 initialize type information for variables x , y , b and c , and statements on line 5 – 7 establish value flow relations. Since both x and y are assigned type A , $x.f$ and $y.f$ are both represented by node $A.f$, thus the set of types reaching $A.f$ is now $\{B, C\}$. (Note this is a more precise result than CHA and RTA which assign $A.f$ with the set $\{A, B, C\}$.) Since $A.m.this$ refers to x , $this.f$ inside method $A.m()$ now refers to $A.f$. Therefore, through $A.m.return$, z receives $\{B, C\}$ as its final set of reaching types.

The result of a context-insensitive subset based points-to analysis [And94] creates a heap abstraction of four objects (shown on line 1 – 4 of Figure 1 as well as the ellipses in Figure 3). These abstract objects are then inter-connected via field store access defined on line 5 – 6. The derived field access from $A.m.this$ to O_2 is shown in dashed arrow. By return of the method call $z = x.m()$, variable z receives O_2 of type B from $A.m.this.f$, which gives a more precise set of reaching types for variable z .

From this example, one may conclude that the imprecision of VTA in comparison with points-to analysis is due to the over abstraction of object types, such that O_1 and O_3 , both of type A , are treated under the same type. Nevertheless, points-to analysis requires to construct a heap abstraction, which brings in extra information, especially when we are only interested in the set of reaching types of a variable.

In this paper we introduce a relational static semantics called Type Flow Analysis (TFA) on program variables and field accesses. Different from VTA, in addition to the binary value flow relation “ \sqsubseteq ” on the variable domain VAR , where $x \sqsubseteq y$ denotes all types that flow to x also flow to y , we also build a ternary

Fig. 4. Type Flow Analysis for variable z in the example

field store relation $\rightarrow \subseteq \text{VAR} \times \mathcal{F} \times \text{VAR}$ to trace the *load* and *store* relationship between variables via field accesses. This provides us additional ways to extend the relations \sqsubseteq as well as \rightarrow . Taking the example from Figure 1, we are able to collect the store relation $x \xrightarrow{f} b$ from line 5. Since $x \sqsubseteq \text{A.m.this}$, together with the implicit assignment which loads f of A.m.return , we further derives $b \sqsubseteq \text{A.m.return}$ and $b \sqsubseteq z$ (dashed thick arrows in Figure 4). Therefore, we assign type B to variable z . The complete reasoning pattern is depicted in Figure 4. Nevertheless, one cannot derive $c \sqsubseteq z$ in the same way.

We have proved that in the context-insensitive inter-procedural setting, TFA is as precise as the subset based points-to analysis regarding type related information. Since points-to analysis can be enhanced with various types of context-sensitivity on variables and objects (*e.g.*, call-site-sensitivity [Shi91, KS13], object-sensitivity [MRR05, SBL11, TYX16] and type-sensitivity [SBL11]), extending type flow analysis with context-sensitivity will only require to consider contexts on variables, which is left for future work.

We have implemented a static type analysis tool for context-insensitive type flow analysis, which is written in Java and aims to analyze Java programs. We run our algorithm on the Jimple, a typed, 3-address, statement based intermediate representation provided by Soot framework [soo]. The implementation has been tested on a collection of benchmark programs from SPECjvm2008 [spe]. We conducted several experiments to compare the efficiency and accuracy with CHA and PTA implemented by Soot. In order to comparing accuracy, we used the instrument technique to implement a dynamic profiling tool, to extract the types of method receiver in runtime. We compared different static results with dynamic record. The experimental result has shown that our approach is more precise than CHA and as precise as PTA. Moreover, TFA reduce significant time cost than PTA. In addition, we found that both PTA and TFA do not provide soundness on all benchmarks. We detail looked into all the unmatched record to find out the reason for unsoundness, which involves some Java advanced features liked reflection, JNI, etc. We will discuss it in the experiment section of this paper.

2. Type Flow Analysis

We define a core calculus consisting of most of the key object-oriented language features, shown in Figure 5, which is designed in the same spirit as Featherweight Java [IPW01]. A program is defined as a code base \bar{C} (i.e., a collection of class definitions) with statement s to be evaluated. To run a program, one may assume that s is the default (static) entry method with local variable declarations \bar{D} , similar to *e.g.*, Java and C++, which may differ in specific language designs. We define a few auxiliary functions. Let function *fields* maps class names to their fields, *methods* maps class names to their defined or inherited methods, and *type* provides types (or class names) for objects. Given class c , if $f \in \text{fields}(c)$, then $\text{ftype}(c, f)$ is the defined class type of field f in c . Similarly, give an object o , if $f \in \text{fields}(\text{type}(o))$, then $o.f$ may refer to an object of type $\text{ftype}(\text{type}(o), f)$ or any of its subclass at runtime. Write \mathcal{C} for the set of classes, OBJ for the set of objects, \mathcal{F} for the set of fields and VAR for the set of variables that appear in a program.¹

In this simple language we do not model common types (*e.g.*, *int* and *float*) that are irrelevant to our analysis. We focus on the reference types which form a class hierarchical structure. We assume a context insensitive setting, such that every variable can be uniquely determined by its name together with its enclosing class and methods. For example, if a local variable x is defined in method m of class c , then $c.m.x$ is the unique representation of that variable. Therefore, it is safe to drop the enclosing class and method name if

¹ Sometimes we mix-use the terms *type* and *class* in this paper when it is clear from the context.

$$\begin{array}{ll}
C & ::= \text{class } c [\text{extends } c] \{ \overline{F}; \overline{M} \} \\
F & ::= c \ f \\
D & ::= c \ z \\
M & ::= m(x) \{ \overline{D}; s; \text{return } x' \} \\
s & ::= e \mid x = \text{new } c \mid x = e \mid x.f = y \mid s; s \\
e & ::= \text{null} \mid x \mid x.f \mid x.m(y) \\
\text{prog} & ::= \overline{C}; \overline{D}; s
\end{array}$$

Fig. 5. Abstract syntax for the core language.

it is clear from the context. In general, we have the following types of variables in our analysis: (1) local variables, (2) method parameters, (3) **this** reference of each method, all of which are syntactically bounded by their enclosing classes and methods.

We define three relation for catching type flow information in programs, a partial order on variables $\sqsubseteq \subseteq \text{VAR} \times \text{VAR}$, a type flow relation $\dashrightarrow \subseteq \mathcal{C} \times \text{VAR}$, as well as a field access relation $\xrightarrow{f} \subseteq \text{VAR} \times \mathcal{F} \times \text{VAR}$, which are initially given as follows.

Definition 1. (Base Relations) These three base relations represent program facts which are generated directly from statements syntactically appearing in programs.

1. $c \dashrightarrow x$ if there is a statement $x = \text{new } c$;
2. $y \sqsubseteq x$ if there is a statement $x = y$;
3. $x \xrightarrow{f} y$ if there is a statement $x.f = y$.

Intuitively, $c \dashrightarrow x$ means variable x may have type c (*i.e.* c flows to x), $y \sqsubseteq x$ means all types that flow to y also flow to x , and $x \xrightarrow{f} y$ means that one may access variable y from field f together with variable x .²

Example 1. We give a snippet code shown in Listing 1 to illustrate the generation of relations. For statement “ $A \ a1 = \text{new } A()$ ” and “ $B \ b1 = \text{new } B()$ ”, we generates two type flow relations “ $A \dashrightarrow a1$ ” and “ $B \dashrightarrow b1$ ”, respectively. We also generate “ $a1 \sqsubseteq a2$ ” and “ $a2 \sqsubseteq a3$ ” from statements “ $a2 = a1$ ” and “ $a3 = a2$ ”. For the field store statement on line 6, we generate a field access relation “ $a1 \xrightarrow{f} b1$ ”. The resulting base relations are shown in Figure. 6(a), where dashed circles refer to types and solid nodes in gray colour represent variables. The type relation, partial order relation and field access relation are shown in dashed arrows, solid arrows labelled “ \sqsubseteq ” and solid arrows labelled with field names.

```

1 public void m() {
2     A a1 = new A();
3     a2 = a1;
4     a3 = a2;
5     B b1 = new B();
6     a1.f = b1;
7     b2 = a1.f;
8     a4 = b2.m2(a3);
9 }
10
11 class B {
12     public A m2(p1) { ... return r; }
13 }

```

Listing 1: An example showing the generation of base relations

In the following we define extended relations to capture propagation of type information inter-procedurally

² Note that VTA treats statement $x.f = y$ in a different way as follows. For each class c that flows to x which defines field f , VTA assigns all types that flow to y also to $c.f$.

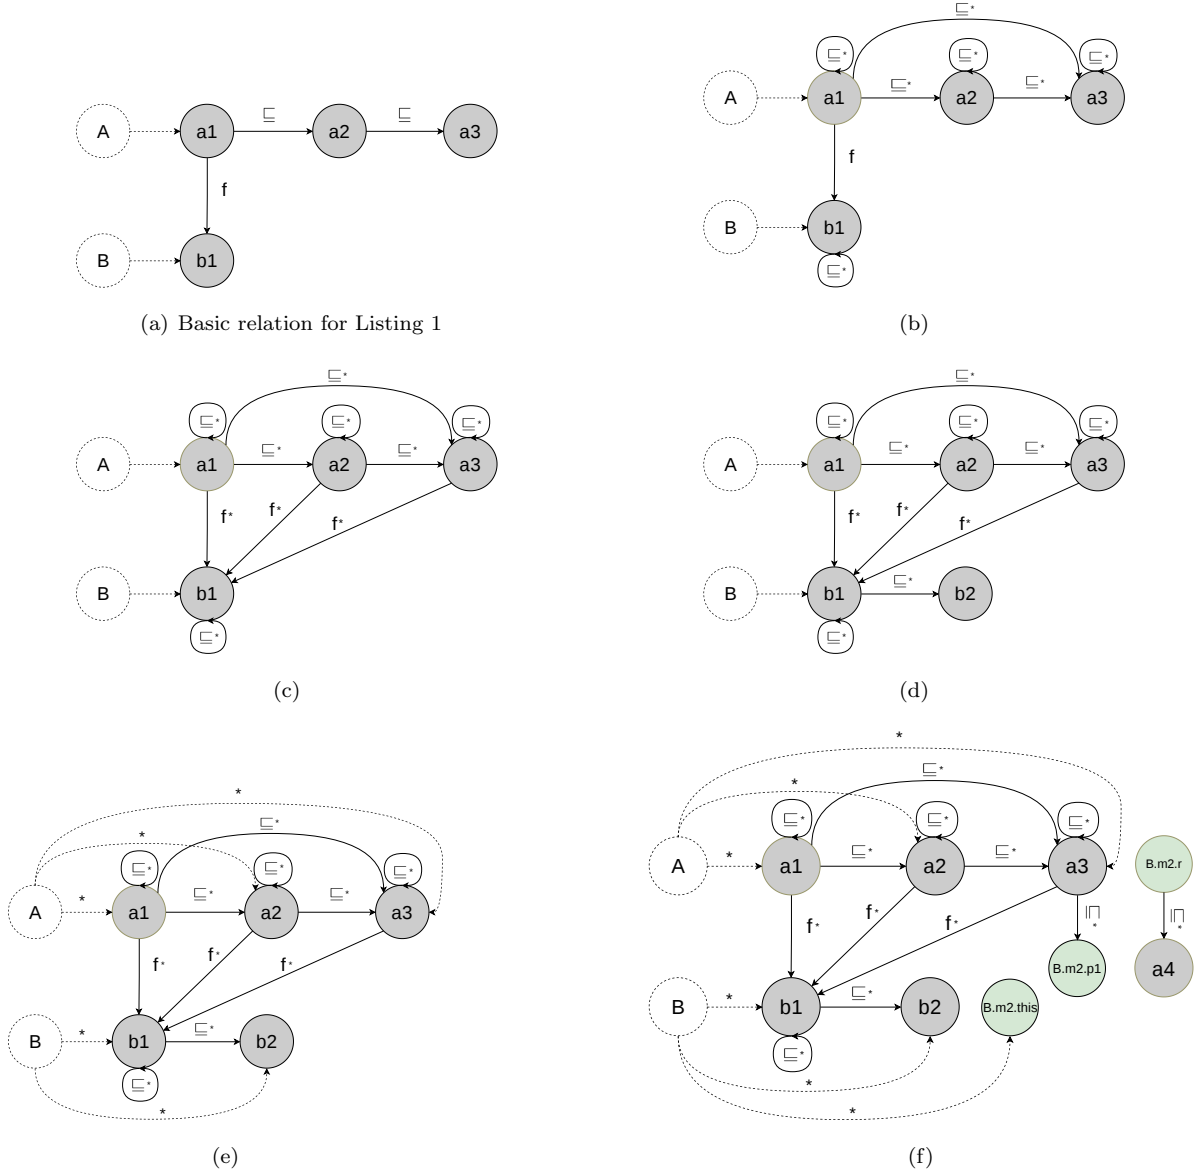

Fig. 6. One round of relation generation for method $m()$ in Listing 1

inside programs. As a convention, R^* (Kleene star) is used to represent the reflexive and transitive closure of relation R . Then we explain the associated operations in Example 2, shown in Figure 6.

Definition 2. (Extended Relations)

1. $y \sqsubseteq^* x$ if $x = y$ or $y \sqsubseteq x$ or $\exists z \in \text{VAR} : y \sqsubseteq^* z \wedge z \sqsubseteq^* x$;
2. $y \xrightarrow{f^*} z$ if $\exists x \in \text{VAR} : x \xrightarrow{f} z \wedge (\exists z' \in \text{VAR} : z' \sqsubseteq^* y \wedge z' \sqsubseteq^* x)$;
3. For all statements $x = y.f$, if $y \xrightarrow{f^*} z$, then $z \sqsubseteq^* x$.
4. $c \dashrightarrow^* y$ if $c \dashrightarrow y$, or $\exists x \in \text{VAR} : c \dashrightarrow^* x \wedge x \sqsubseteq^* y$;

statement	Points-to constraints
$x = \text{new } c$	$o_i \in \Omega(x)$
$x = y$	$\Omega(y) \subseteq \Omega(x)$
$x = y.f$	$\forall o \in \Omega(y) : \Phi(o, f) \subseteq \Omega(x)$
$x.f = y$	$\forall o \in \Omega(x) : \Omega(y) \subseteq \Phi(o, f)$
$x = y.m(z)$	$\forall o \in \Omega(y) : \begin{cases} \Omega(z) \subseteq \Omega(\text{param}(\text{type}(o), m)) \\ o \in \Omega(\text{this}(\text{type}(o), m)) \\ \forall x' \in \text{return}(\text{type}(o), m) : \\ \Omega(x') \subseteq \Omega(x) \end{cases}$

Fig. 7. Constraints for an context-insensitive points-to analysis.

5. The type information is used to resolve each method call $x = y.m(z)$.

$$\begin{aligned} &\forall c \dashrightarrow^* y : \\ &\forall m(z')\{\dots \text{return } x'\} \in \text{methods}(c) : \begin{cases} z \sqsubseteq^* c.m.z' \\ c \dashrightarrow^* c.m.\text{this} \\ c.m.x' \sqsubseteq^* x \end{cases} \end{aligned}$$

Regarding the extended relations given in Definition 2, we provide the following intuitions. Definition 2(1) computes the reflexive and transitive closure of the relation \sqsubseteq . In Definition 2(2), with the existence of z' , variables x and y are in the *may-alias* relation, therefore, all that is accessible by x via field f is also accessible by y via f . This rule is designed to extend the field access relation. Definition 2(3) loads z to x (via f) from y , provided that z is accessible by y via f . Definition 2(4) extends the type flow relation by taking advantage of the extended partial order \sqsubseteq^* on variables. Definition 2(5) deals with inter-procedural type flow, which defines three extensions for parameter variables, **this** references and **return** variables, respectively.

Example 2. We describe the process of generating extended relations as depicted in Figure 6. Although the actual computation may take a number of iterations to reach a fixpoint, to make the process more understandable, we try to sketch in separate how each rule given in Figure 6 works. Initially, the base relation for Listing 1 is given in Figure 6(a). Definition 2(1) extends the base relation \sqsubseteq into \sqsubseteq^* , as shown in Figure 6(b). Definition 2(2) extends the field access relation, resulting in Figure 6(c). By applying Definition 2(3), we further extends \sqsubseteq^* through the existing field access relation, reaching the graph in Figure 6(d). Then Definition 2(4) propagates the type flow relation \dashrightarrow^* by considering the existing partial order relation and field access relation on variables, as shown in Figure 6(e). In Figure 6(f) we further enrich the relations for inter-procedural type flow, where the statement “ $a4 = b2.m2(a3)$ ” triggers the invocation of method $m2()$ in class B , from which we establish “ $a3 \sqsubseteq^* B.m2.p1$ ”, “ $B \dashrightarrow^* B.m2.\text{this}$ ” and “ $B.m2.r \sqsubseteq^* a4$ ”, where $B.m2.p1$ and $B.m2.r$ are respectively the virtual parameter of method $m2()$ and the return variable of method $m2()$. In fact, Figure 6(f) depicts the smallest type flow model satisfying all constraints given in Definition 2 regarding the program in Listing 1.

In order to compare the precision of TFA with points-to analysis, we present a brief list of the classical subset-based points-to rules for our language in Figure 7, in which Ω (the var-points-to relation) maps a reference to a set of objects it may point to, and Φ (the heap-points-to relation) maps an object and a field to a set of objects. The points-to rules are mostly straightforward, except that $\text{param}(\text{type}(o), m)$, $\text{this}(\text{type}(o), m)$ and $\text{return}(\text{type}(o), m)$ refer to the formal parameter, **this** reference and **return** variable of method m of the class for which object o is declared, respectively.

To this end we present the first result of the paper, which says type flow analysis has the same precision regarding type based check, such as call site resolution and cast failure check, when comparing with the points-to analysis.

Theorem 1. In the context-insensitive setting, for all variables x and classes c , $c \dashrightarrow^* x$ in TFA iff there exists an object abstraction o of c such that $o \in \Omega(x)$ in points-to analysis.

Proof. (sketch) First we assume that for each class c , every object creation site $x = \text{new } c_i$ at line i defines

a mini-type c_i , and if the theorem is satisfied in this setting, a subsequent merging of mini-types into class c will preserve the result.

Moreover, we only need to prove the result in the intraprocedural setting (*i.e.* Lemma 1). Because if in the intraprocedural setting the two systems have the same smallest model for all methods, then at each call site $x = y.m(a)$ both analyses will assign y the same set of classes and thus resolve the call site to the same set of method definitions, and as a consequence, each method body will be given the same set of extra conditions, thus all methods will have the same initial condition for the next round iteration. Therefore, both inter-procedural systems will stabilize at the same model. \square

The following lemma focuses on the key part of the proof for Theorem 1, which shows that TFA and points-to analysis are equivalent regarding call site resolution within a function.

Lemma 1. In a context-insensitive intraprocedural analysis where each class c only syntactically appears once in the form of `new c`, for all variables x and classes c , $c \dashrightarrow^* x$ iff there exists an object abstraction o of type c such that $o \in \Omega(x)$.

Proof. Since those constraints of the points-to analysis establish the smallest model (Ω, Φ) with $\Omega : \text{VAR} \rightarrow \text{OBJ}$ and $\Phi : \text{OBJ} \times \mathcal{F} \rightarrow \mathcal{P}(\text{OBJ})$, and the three relations of type flow analysis also define the smallest model that satisfies Definition 1 and Definition 2, we prove that every model established by points-to analysis constraints is also a model of TFA, and vice versa. Then the least model of both systems must be the same, as otherwise it would lead to contradiction.

(\star) For the ‘only if’ part (\Rightarrow), we define a function $\text{Reaches}(x) = \{c \mid c \dashrightarrow^* x\}$ which maps a variable to its reaching types in TFA, and assume a bijection $\xi : \mathcal{C} \rightarrow \text{OBJ}$ that maps each class c to the unique (abstract) object o that is defined (and $\text{type}(o) = c$). Then we construct a function $\text{Access} : \mathcal{C} \times \mathcal{F} \rightarrow \mathcal{P}(\mathcal{C})$ and show that $(\xi(\text{Reaches}), \xi(\text{Access}))$ satisfies the points-to constraints. Define $\text{Access}(c, f) = \{c' \mid x \xrightarrow{f}^* y \wedge c \in \text{Reaches}(x) \wedge c' \in \text{Reaches}(y)\}$. We prove the following cases according to the top four points-to constraints in Figure 7.

- For each statement $x = \text{new } c$, we have $\xi(c) \in \xi(\text{Reaches}(x))$, as $c \in \text{Reaches}(x)$ by Definition 1(1);
- For each statement $x = y$, we have $\text{Reaches}(y) \subseteq \text{Reaches}(x)$ and $\xi(\text{Reaches}(y)) \subseteq \xi(\text{Reaches}(x))$, as $y \sqsubseteq^* x$ by Definition 1(2);
- For each statement $x.f = y$, we have $x \xrightarrow{f} y$ by Definition 1(3), therefore $x \xrightarrow{f}^* y$. We need to show that for all $c \in \text{Reaches}(x)$, $\xi(\text{Reaches}(y)) \subseteq \xi(\text{Access}(c, f))$. Let $c \in \text{Reaches}(x)$, and $c' \in \text{Reaches}(y)$, by definition we have $c' \in \text{Access}(c, f)$. Therefore $\text{Reaches}(y) \subseteq \text{Access}(c, f)$. Then consequently, $\xi(\text{Reaches}(y)) \subseteq \xi(\text{Access}(c, f))$.
- For each statement $x = y.f$, for all $c \in \text{Reaches}(y)$, we need to show $\xi(\text{Access}(c, f)) \subseteq \xi(\text{Reaches}(x))$, or equivalently, $\text{Access}(c, f) \subseteq \text{Reaches}(x)$. Let $c' \in \text{Access}(c, f)$, then by definition of Access , there exist z, z' such that $c \in \text{Reaches}(z)$, $c' \in \text{Reaches}(z')$ and $z \xrightarrow{f}^* z'$. Since each type is uniquely created in the current setting, *i.e.* there exists a statement $z'' = \text{new } c$ such that $z'' \sqsubseteq^* y$ and $z'' \sqsubseteq^* z$. Then by $z \xrightarrow{f}^* z'$ and Definition 2(2), we have $y \xrightarrow{f}^* z'$. Then by $x = y.f$ and Definition 2(3), we have $z' \sqsubseteq^* x$. Therefore $c' \in \text{Reaches}(x)$.

(\star) For the ‘if’ part (\Leftarrow), let (Ω, Φ) be a model that satisfies all the top four constraints defined in Figure 7, and a bijection $\xi : \mathcal{C} \rightarrow \text{OBJ}$ between class names and objects, we show that the following constructed relations (\dashrightarrow^* , \sqsubseteq^* , \xrightarrow{f}^*) derived from (Ω, Φ) satisfy the (intraprocedural) constraints defined for the base relations (*i.e.* Definition 1 and the extended relations (*i.e.* Definition 2) for TFA.

- For all types c and variables x , $c \dashrightarrow^* x$ iff $\xi(c) \in \Omega(x)$;
- For all variables x and y , $x \sqsubseteq^* y$ iff $\Omega(x) \subseteq \Omega(y)$;
- For all variables x and y , and for all fields f ,

- $x \xrightarrow{f} y$ iff for all $o \in \text{OBJ}$, $o \in \Omega(x)$ implies $\Omega(y) \subseteq \Phi(o, f)$.
- $x \xrightarrow{f}^* y$ iff there exists $o \in \Omega(x)$, $\Omega(y) \subseteq \Phi(o, f)$.

We check the following cases for the three relations \dashrightarrow^* , \sqsubseteq^* and $\xrightarrow{*}$ that are defined from the above.

- **Def 1(1).** For each statement $x = \text{new } c$, we have $\xi(c) \in \Omega(x)$, so $c \dashrightarrow^* x$ by definition.
- **Def 1(2).** For each statement $x = y$, we have $\Omega(y) \subseteq \Omega(x)$, therefore $y \sqsubseteq^* x$ by definition.
- **Def 1(3).** For each statement $x.f = y$, we have for all $o_1 \in \Omega(x)$ and $o_2 \in \Omega(y)$, $o_2 \in \Phi(o_1, f)$, which derives $x \xrightarrow{*} y$ by definition.
- **Def 2(1).** It is obvious that \sqsubseteq^* is transitive and reflexive, which is by \subseteq being transitive and reflexive.
- **Def 2(2).** W.l.o.g., for all $x \in \text{VAR}$, $\Omega(x) \neq \emptyset$, since the included type could be from **new**, or from method parameter passing or return. Given $x \xrightarrow{*} z$, $z' \sqsubseteq^* y$ and $z' \sqsubseteq^* x$, we need to show $y \xrightarrow{*} z$. Let $\xi(c) \in \Omega(z')$, then $\xi(c) \in \Omega(x)$ and $\xi(c) \in \Omega(y)$. Then $\Omega(z) \subseteq \Phi(\xi(c), f)$ by $\xi(c) \in \Omega(x)$ and $x \xrightarrow{*} z$. Therefore we have $y \xrightarrow{*} z$ by the existence of $\xi(c)$.
- **Def 2(3).** For each statement $x = y.f$, given $y \xrightarrow{*} z$, we need to show $z \sqsubseteq^* x$. Equivalently, by definition there exists $o \in \Omega(y)$ such that $\Omega(z) \subseteq \Phi(o, f)$. Given the statement $x = y.f$, for all $o' \in \Omega(y)$ $\Phi(o', f) \subseteq \Omega(x)$, therefore by existence of o , we have $\Omega(z) \subseteq \Omega(x)$, the definition of $z \sqsubseteq^* x$.
- **Def 2(4).** The first case that $c \dashrightarrow y$ implies $c \dashrightarrow^* y$ is trivial. Let $c \dashrightarrow^* x$ and $x \sqsubseteq^* y$, we need to show that $c \dashrightarrow^* y$. Since $\xi(c) \in \Omega(x)$ and $\Omega(x) \subseteq \Omega(y)$, we have $\xi(c) \in \Omega(y)$, which is equivalent to $c \dashrightarrow^* y$, as required.

□

3. Implementation

The analysis algorithm is written in Java, and is implemented in the Soot framework, the most popular static analysis framework for Java. We use jimple as intermediate representation (IR). We do not take common types (*e.g.* , **int** and **float**) under our consideration, since these are irrelevant to our analysis. Our work consists of two parts. The first part implements the static type flow analysis algorithm introduced in previous sections, based on the information extracted from jimple IR and computes a set of types for each reference variable in the program. The second part instantiates a dynamic profiler that collects type-related information, which is then used to analyze the precision of the static analysis algorithm, as well as making comparison to other type analysis algorithms including CHA, RTA, VTA and PTA. A more detailed description is given as follows, in Section 3.1 and Section 3.2.

3.1. Static Analysis

Our static analysis tool takes Java bytecode files as input. Any other format of Java code is acceptable provided that it can be translated to jimple representation by Soot (*e.g.* , jar files). The implementation of our static analysis tool can be described in the following four steps.

1. Code translation: Target code is loaded by Soot and translated to jimple IR.
2. Basic relation extraction: We traverse the jimple IR to generate all basic relations by definition.
3. Fixpoint calculation: After basic relations are generated, we use the extended relation rules to perform fixpoint calculation.
4. Result extraction: After all required analysis is done, we extract the set of reaching types as final result.

Note that since our analysis is inter-procedural, type information for a receiver of a call site can be used to resolve potential callee methods, which further help to propagate type information from actual parameters to virtual parameters and from return variables back to the caller statement. Since the additional inter-procedural type flow may incrementally help to enrich type information at call sites, the type flow process is mutually recursive among call sites and defined methods. Fig 8 shows the whole process of our static analysis tool. Data input and generated are represented in dash arrow. The final result is generated in the “Result Extraction” phase and represented in green background.

In order to achieve an acceptable performance, we make conservative treatments on array accesses and

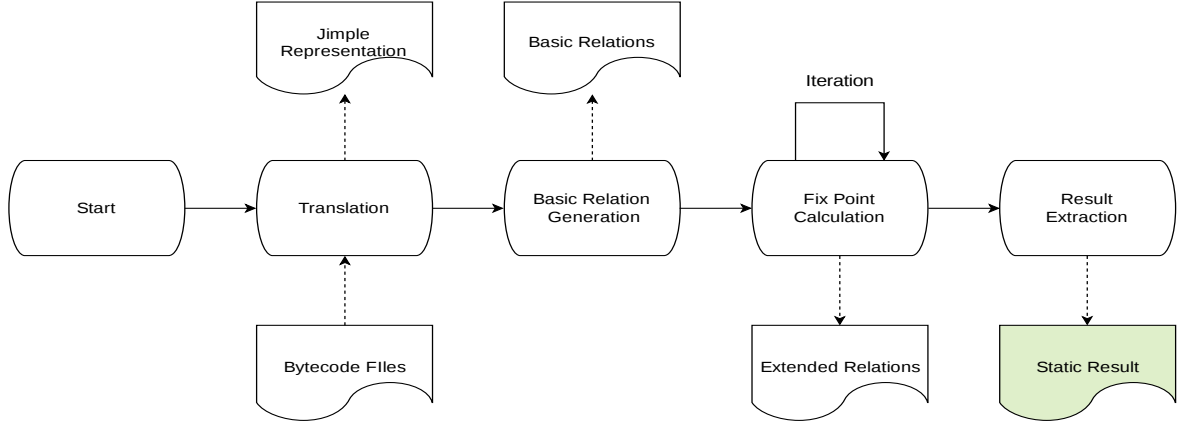

Fig. 8. Process of static analysis tool

library calls. We choose not to analyze method invocation from advanced Java language features such as reflection and JNI, and leave such calls as unresolved. Therefore, our methodology is unsound regarding these features, similar to most existing tools for Java program analysis, to the best of our knowledge. (C.f. an interesting discussion regarding soundness [LSS⁺15]) We will provide a detailed analysis regarding our conservative approach on the impact to the performance of our implemented TFA algorithm in Section 4.

3.2. Dynamic Profiling

We apply dynamic analysis to collect the groundtruth of a program’s run-time behaviour, such as an actual type a given variable has during an execution and an actual method being called at a particular program location. To build up a baseline for measuring the precision of TFA, we have implemented a dynamic profiling tool that records the actual types that a variable may have at run-time, in particular when the variable is a receiver at a call site. Based on the Soot framework, We instrument the jimple statements of the target benchmark programs that are subsequently tested in our experiment. After the instrumentation phase, run-time types are collected during the benchmark execution and are dumped to the output. We consider the collected variable-type relation as the groundtruth and compare it with the results generated by our static TFA algorithm, with details presented in section 4.2. For an effective instrumentation, we consider the following four possible ways on how to instrument a Java program.

Insert First. The type-recording statements are inserted as the first statement of each method block so that the type of `this` reference in that method will be recorded. Note that a receiver is always passed into `this` reference in a callee method, unless the method is static.

Insert Before. New statements are inserted before each call site to collect the receiver type. This is more straightforward than *Insert First*, as we do not need to find the types of `this` variables in callees.

Insert Last. Similar to *Insert First*, except that statements are inserted after the last statement of a method block. We also record the type of `this` reference.

Insert After. In this way we insert statements right after each call site to record the type of the receiver, which is similar to *Insert Before*. We choose to adopt this scheme and the reason is given as follows.

According to the Java specification, the first statement of each constructor should be either another constructor of its own or its super class. Therefore, we would get a *JVM violation* error if we instrument a statement before the first statement in a constructor. We illustrate this problem in an example given in Listing 2. Due to this restriction, both *Insert First* and *Insert Before* schemes cannot be applied. For the remaining to schemes, we choose *Insert After* over *Insert Last*, so that a type can be straightforwardly collected and bundled with its receiver. As an example, the code before and after instrumentation are shown in Listing 3 and Listing 4, respectively. For Listing 4, at line 5, the function `RecordUtils.id()` takes an invocation expression (*invokeExprssion*) and a method receiver (*b*) as parameters and return an unique representation string for this invocation. In this example, the collected unique representation is `A:m1:b:B:m2:4`. This means

b calls method $m2$ of class B , at line 4 within method $m1$ of class A . It also shows that b is of type B at this program location.

```

1  class A {
2      public A() {
3          //insert statements here will violate JVM specification
4          super();    //invoke super class constructor
5      }
6      public A(int i) {
7          //insert statements here will violate JVM specification
8          this();    //inoveke another constructor of its own
9      }
10 }

```

Listing 2: Java specification on constructor

```

1  class A {
2      public void m1() {
3          B b = new B();
4          b.m2();    //invocation here
5      }
6  }

```

Listing 3: Example code before instrumentation

```

1  class A {
2      public void m1() {
3          B b = new B();
4          b.m2();    //invocation here
5          String record = RecordUtils.id(InvokeExpression, b);
6          RecordUtils.record(record);
7      }
8  }

```

Listing 4: Example code after instrumentation

4. Evaluation

We evaluate our approach by measuring its performance on SPECjvm2008 [spe], which contains 12 benchmark programs in total, adapted from real life applications. We conduct all of our experiments on a laptop equipped with an Intel i5-8250U CPU at 1.60 GHz and 8 GB memory, running Ubuntu 16.04LTS with OpenJDK 1.8.0.

We compare our approach against Class Hierarchy Analysis (CHA) , Variable Type Analysis (VTA) and context-insensitive points-to analysis (PTA). Among these compared approaches, we use the hierarchy structure provided in Soot framework to implement CHA. The VTA and the points-to analysis are implemented by Soot team. We discover that since the VTA implementation in Soot is only an optional subprocess used to generate callgraph for points-to analysis, the generated call graph is accessible by developer, and the general application interface of VTA is invisible to normal Soot users. Due to this reason, we are unable to apply VTA as an independent process to measure its performance on the SPECjvm2008 benchmark programs. Nevertheless, we managed to compare our results with the call graph that is generated by the VTA subprocess, as shown in Figure 10 and Figure 11.

The choice of comparing with the context-insensitive points-to analysis implementation in Soot is due to our approach also being context-insensitive, thus the results from both approaches are comparable. In

particular, the iterative algorithm for points-to analysis provided by the Soot team adopts a more space-efficient *bit vector* data structure, as the points-to computation usually consumes more memory than TFA, to avoid *Out-Of-Memory* error. For the implementation of TFA, we apply the usual data structure (*i.e.*, *HashSet*).

In the following tables listed in Figure 9, Figure 10 and Figure 11, we use the keywords **CHA**, **VTA**, **PTA** and **TFA** to refer to the results from class hierarchy analysis, variable type analysis, points-to analysis and type flow analysis, respectively. During the evaluation the following two research questions are addressed.

- **RQ1** How efficient is our type flow analysis based approach compared with the traditional class hierarchy analysis and points-to analysis?
- **RQ2** How accurate is our algorithm comparing with the other approaches?

We try to provide answers to these two questions as discussed in section 4.1 and section 4.2, respectively.

4.1. Analysis on Performance

We have executed all SPECjvm2008 benchmark programs 10 times with the CHA, PTA and TFA algorithms. Then we calculate the average time consumption (in seconds) as displayed at column $T_{CHA}(s)$, $T_{PTA}(s)$ and $T_{TFA}(s)$ of the Table in Fig. 9. We also list the sizes of the generated relations (*i.e.*, the type flow relation ' \dashrightarrow ', variable partial order ' \sqsubseteq ' and the field access relation ' \rightarrow '), which provide an estimation of input size for the problems we are treating. The result confirms that our approach consumes more time than CHA, which is reasonable, as CHA does not apply any propagation on types, but only analyzes the class and interface hierarchical structure.³ TFA is in general more efficient than points-to analysis. In general, the runtime cost of TFA increases on benchmarks with larger size of generated relations as well as higher relational complexity, as most of the time in TFA is spent on calculating a fixpoint (*e.g.*, on benchmark *startup* the number of generated relations reach to 50,478, on which TFA spends the most amount of time(19.75s) among all benchmarks). We conjecture that PTA is slower than TFA because it requires extra time for maintaining and updating a heap abstraction.

³ Note that we have implemented the current CHA algorithm by using the class hierarchy structure provided in the Soot framework. The default CHA implementation in Soot runs much slower, as shown in our earlier experiment result in [ZZ19].

Fig. 10. Recall on different analysis

4.2. Analysis on Accuracy

In this section we address the second question about accuracy in two perspectives: recall and precision. Firstly, the definitions are given in Equation 1 and Equation 2, respectively.

$$recall = \frac{TP}{TP + FN} \quad (1)$$

$$precision = \frac{TP}{TP + FP} \quad (2)$$

Here, *TP* stands for *true positive*. This refers to the number of call edges identified by the analysis which also happens during program execution. *FN* stands for *false negative*, which is the number of call edges missed by the analysis. *FP* (*false positive*) refers to the number of call edges erroneously generated by the analysis. In general, a sound analysis should catch all existing runtime type information, *i.e.*, the *recall* should be 100%. On the other hand, *precision* is defined as percentage of reported types that are correctly generated by the analysis. In general, given *recall* fixed, a more precise algorithm should generate a smaller set of types for each calling variable. We present recall and precision of the given approaches, as displayed in Fig. 10 and Fig. 11, respectively.

Regarding soundness, we use the call edges generated by the dynamic profiling (described in Section 3.2) as baseline, shown at the **Dynamic** columns of Figure 10 and Figure 11. In general, CHA is able to achieve nearly 100% recall, but VTA, TFA and PTA all fail to achieve 100% recall except for the **helloworld** program. TFA is able to achieve above 90% recall on average, higher than VTA and PTA (20% more recall on about half of the benchmark programs). Regarding precision, TFA achieves about 80% on average, lower than VTA and PTA, but in general higher than CHA.

Given that TFA achieves a higher recall than VTA and PTA, we have identified a few possible reasons. Firstly, VTA and PTA implemented by the Soot team have applied an on-the-fly reachability analysis which rules out a portion of methods which are reported as unreachable. Therefore the unreachable methods would not be analyzed, and variables receiving their type from JDK would be assigned with possible types based on the preprocessing from Soot. For TFA, we have implemented a conservative approach on JDK library functions which always returns the predefined types in API together with all their subtypes. We also implemented a conservative array analysis which may also contribute to higher recall as well as lower precision. We also note that we have not implemented special treatment on advanced Java language features including Java Reflection API and Java Native Interface calls, as well as more detailed analysis in the JDK library and side effects produced by callbacks from invisible codes (*e.g.* from JDK library and reflective calls), which all contributed *FN* instances, such that TFA still does not produce a sound result (*i.e.* 100% recall) on

most benchmark programs.⁴ For a more detailed explanation regarding the special treatment implemented in TFA, we refer to Section 4.3.

We have also investigated why CHA also missed 8 call edges on the benchmarks **compiler** and **startup**. The one missed on **compiler** is caused by the incomplete default hierarchy structure provided by the Soot framework. As an example, we put on a hierarchy structure of *javax.tools.JavaFileManager\$Location* in JDK, as shown in Fig. 12. Note that variable *x* is declared of type *javax.tools.JavaFileManager\$Location* in benchmark **compiler**. However, the hierarchy structure provided by the Soot framework does not properly include *javax.tools.DocumentationTool\$Location* or *javax.tools.StandardLocation* as subclasses of *javax.tools.JavaFileManager\$Location*. Hence, these 2 types are missed by CHA for variable *x*. The other 7 missed types in CHA are due to that the Soot framework mistakenly changes the name of a few temporary variables (e.g., variable \$68 is changed to \$58), which can be confirmed by reading the jimple representation.

Over all, for a comparison of the algorithms regarding precision, the experiment result has shown that in general TFA can achieve higher precision than CHA, since CHA blindly includes all the subclass of a declared class to the result. At the same time, TFA produces lower precision than VTA and PTA due to its decisive trade-off between recall and precision. The imprecision is mainly due to our approximation on library invocation and array (we defer a detailed discussion to section 4.3). These conservative treatment has raised up recall but lowered precision at the same time. For example, on benchmark **compiler**, the recall of TFA achieves 0.955, which is much higher than VTA(0.595) and PTA(0.616), as TFA catches more call edges than VTA(175) and PTA(165). As a result, TFA generates more records than VTA(89) and PTA(96), with a lower precision of 0.829. Focusing on the benchmark **serial** and **startup** as shown in Fig. 11. We

⁴ As we mentioned earlier, most existing tools for Java program analysis are not sound, but soundy [LSS⁺15].

Fig. 14. Precision without library approximation

notice that PTA has generated lots of FPs, which lowers its precision to 0.014 and 0.386. This is caused by Soot’s conservative treatment on Java *Exception* and preprocess on some specific library calls.

Due to the conservative approach on JDK library function, the TFA analysis achieves higher recall with the price of lower precision in comparison to VTA and PTA. Note that in theory context insensitive TFA is equivalent to context insensitive PTA and is more precise than VTA, as studied in Section 2. In order to make the implementations more comparable, we modified the implementation of TFA by removing the library call approximation to JDK. As shown in Figure 13 and Figure 14, without the conservative treatment on JDK library, in general TFA has a comparable precision and recall to VTA and PTA on the given benchmark suite. To explain the reason that VTA and PTA marginally outperform TFA in a few benchmarks, we refer to the optimizations implemented by the Soot team on array operations and certain reflective calls that are used by the VTA and PTA processes.

4.3. A Detailed Analysis on TFA’s FP and FN

In this section we briefly review the factors that hamper the performance of our type flow analysis.

Reflective calls. Reflection is an advanced feature in the Java programming language which provides the ability to inspect and manipulate a Java class at runtime. It brings in extra complexity to programs and its behaviour is hard to predict statically. In Listing 5 we show a sample code using reflection in one of the benchmark programs to discuss how reflection works and what our treatment is. Note that this is an example

we have simplified from the real code in order to concentrate on the main functionality of reflection. We discuss in three cases.

- **Object Creation.** From line 6 to line 10, a new object of type *SPECJVMBenchmarkBase* is created by method *newInstance()* on variable *c* at line 10, where *c* is an object of *Constructor* type and it refers to a specific constructor of class *SPECJVMBenchmarkBase*. In the TFA analysis, we discard the type information of the new object in such a case because it is usually difficult to statically identify which constructor is invoked. For example, At line 6, if statement *Class.forName()* receives a string argument from the outside such as file input and user input, it is usually not easy to find out the real type of *benchmarkClass*. As a result, the run time type of *c* and *benchmark* cannot be identified.
- **Method Invocation.** After a new object is instantiated, we can get an object of *Method* type, referring to a specific method of a class, and call this method by the method *invoke()* (line 17). This effect is similar to a normal invocation at line 12. The invocation receiver is passed to the first argument of *invoke()*. In a case of static invocation, a **null** reference is passed to the first argument. We do not consider this way of reflective method invocation in TFA, for the same reason as we discuss about object creation.
- **Field Modification.** The way to change a field using reflection is similar to processing method invocation. The line 24 – 25 illustrate changing value of field *f* from object *benchmark* to a new object. We do not handle this effect in TFA, either.

```

1 public static void runSimple(Class benchmarkClass, String [] args) {
2     ...
3     ...
4     Class [] cArgs = { BenchmarkResult.class, int.class };
5     Object [] inArgs = { bmResult, Integer.valueOf(1) };
6     Class benchmarkClass = Class.forName("spec.harness.SpecJVMBenchmarkBase");
7     Constructor c = benchmarkClass.getConstructor(cArgs);
8
9     // Object creation using reflection
10    SpecJVMBenchmarkBase benchmark = (SpecJVMBenchmarkBase)c.newInstance(inArgs);
11    // normal method invocation
12    benchmark.harnessMain();
13
14    // method invocation
15    Method harnessMain = benchmarkClass.getMethod("harnessMain", new Class [] {});
16    // just like line 11 but in reflection manner
17    harnessMain.invoke(benchmark, new Object [] {});
18
19    Method setup = benchmarkClass.getMethod("setupBenchmark", new Class [] {});
20    // static invocation
21    setup.invoke(null, new Object [] {});
22
23    // field modification
24    Field f = benchmarkClass.getField("f");
25    f.set(benchmark, new Object());
26 }

```

Listing 5: Example code of reflection

JNI calls. Java Native Interface (JNI) is a standard Java programming interface which provide ability for Java code to interoperate with application or library written in other programming languages, such as C, C++ or assembly. We show the usage of JNI in Listing 6. Method *m()* is defined as a native method and should not be implemented in Java. This program will load a native library named *lib*, in which the method *m()* is implemented in a different program language. We do not consider JNI calls in our algorithm since the code is not written in Java. Analyzing that code and the communication between Java and other languages

are out of our research scope. As a consequence, the effect of the invocation $a.m()$ at line 8 is not analyzed by TFA.

```

1 public class A {
2     public native void m();
3     static {
4         System.loadLibrary("lib");
5     }
6     public static void main(String[] args) {
7         A a = new A();
8         a.m(); <—
9     }
10 }

```

Listing 6: Example code of JNI

Library call. Library calls included in an application (*e.g.*, JDK libraries, third-party libraries) are usually in pre-compiled bit code format, and their source code is often large and not made explicitly available. Listing 7 shows a common case of JDK invocation. We do not analyze the detailed logic inside library code which are written at line 10 – 11. Instead, we perform an over approximation on library invocation, based on the method definition which appears at line 9. We assume that library invocation will return the definition type and any subtype of this definition type as the result type. For Listing 7, $sb2$ will receive $\{StringBuilder, any_subtype_of_StringBuilder\}$ as the set of reaching types under this strategy.

```

1 import java.lang.StringBuilder;
2
3 public void m() {
4     StringBuilder sb = new StringBuilder();
5     StringBuilder sb2 = sb.append("abc"); <—
6 }
7
8 // @Override
9 // public StringBuilder append(String str) {
10 //     ...
11 //     ...
12 // }

```

Listing 7: Example of JDK library call

Array approximation. We perform a conservative treatment on array accesses in the way that all type information that flows to one member of an array flows to all members of that array. Codes in Listing 8 are used to explain how this approximation works. In this example, type information of A and B flow to the first member and the second member of array arr , respectively. We treat in the way that both A and B flow to the array arr , so that loading an element of arr receives both types (*i.e.* b receives $\{A, B\}$ as the set of reaching types, which is the same set of types that array arr can access).

```

1 public void m() {
2     Object[] arr = new Object[2]{};
3     arr[1] = new A();
4     arr[2] = new B();
5     Object b = arr[1]; <—
6 }

```

Listing 8: Example of array access

Callbacks. A callback function is known as a “call-after” function, which is widely used in object-oriented styled programming. By passing an argument to a method, the receiver may be used inside the callee to trigger a callback invocation. In functional language a callback function can be passed as argument directly. Listing 9 illustrates the callback mechanism, where function *callback()* of class *B* is invoked after the invocation of *trigger()* of class *A*. Since we do not analyze the effect of reflection calls, JNI calls and library calls, we are unable to catch the type flow information inside *a.trigger(b)* if it happens to be one of these calls (*e.g.* , *trigger()* is a method of a library class). Note that we only conservatively approximate on the return type of a library invocation.

```

1  class A {
2      public void trigger(B b) {
3          b.callback(); // here the callback function actually executes
4      }
5  }
6
7  class B {
8      public void callback() {...}
9      public void static main() {
10         A a = new A();
11         B b = new B();
12         a.trigger(b);
13     }
14 }

```

Listing 9: Callback mechanism

Exception handling. PTA implemented by Soot conservatively add all the subclass of *Throwable* to the possible types of variable *t* if method *m()* is reachable. Since *Throwable* is the superclass of all errors and exceptions in Java. These result set could be pretty large. In general it would reach to more than 200. That means if we only have a single dynamic record for this invocation statement, the precision will be reduced significantly.

```

1  class A {
2      void m() {
3          try {
4              ...
5          } catch (Throwable t) {
6              t.printStackTrace();
7          }
8      }
9  }

```

Listing 10: Java Exception

5. Related Work

There are not many works focusing on general purpose call graph construction algorithms, and we give a brief review of these works first.

As stated in the introduction, Class Hierarchy Analysis (CHA) [DGC95, Fer95], Rapid Type Analysis (RTA) [BS96] and Variable Type Analysis (VTA) [SHR⁺00] are efficient algorithms that conservatively resolves call sites without any help from points-to analysis. Grove et al. [GD⁺97] introduced an approach to model context-sensitive and context-insensitive call graph construction. They define call graph in terms of three algorithm-specific parameter partial orders, and provide a method called Monotonic Refinement, potentially adding to the class sets of local variables and adding new contours to call sites, load sites, and

store sites. Tip and Palsberg [TP00] Proposed four propagation-based call graph construction algorithms, CTA, MTA, FTA and XTA. CTA uses distinct sets for classes, MTA uses distinct sets for classes and fields, FTA uses distinct sets for classes and methods, and XTA uses distinct sets for classes, fields, and methods. The constructed call graphs tend to contain slightly fewer method definitions when compared to RTA. It has been shown that associating a distinct set of types with each method in a class has a significantly greater impact on precision than using a distinct set for each field in a class. Reif et al. [REH⁺16] study the construction of call graphs for Java libraries that abstract over all potential library usages, in a so-called *open world* approach. They invented two concrete call graph algorithms for libraries based on adaptations of the CHA algorithm, to be used for software quality and security issues. In general they are interested in analyzing library without knowing client application, which is complementary to our work that has focus on client program while treating library calls as end nodes.

Call graphs may serve as a basis for points-to analysis, but often a points-to analysis implicitly computes a call graph on-the-fly, such as the context insensitive points-to algorithm implemented in Soot using SPARK [LH03]. Most context-sensitive points-to analysis algorithms (e.g., [MRR05, SB06, SBL11, TYX16]) progress call edges together with value flow, to our knowledge. The main distinction of our approach from these points-to analysis is the usage of an abstract heap, as we are only interested in the actual reaching types of the receiver of a call. Nevertheless, unlike CHA and VTA, our methodology can be extended to context-sensitive settings.

Regarding the treatment of flow analysis in our algorithm, downcast analysis has been studied in region inference which is a special memory management scheme for preventing dangling pointers or improving precision in garbage collection in object-oriented programming languages [BSWBR03, CCQR04]. These works are type-based analysis, while our methodology belongs to traditional static program analysis. Similar ideas regarding value flow can also be found in the graph-reachability based formulation (e.g. [Rep97, LSXX13]) to which all distributed data flow analyses can be adopted.

Runtime profiling data can be recorded and used to compare with static analysis result. Furthermore, these runtime data can help static algorithms to increase precision and achieve adaptive ability. In general there are two ways to record runtime profiling data for Java programs, collecting from Java VM [SWB⁺14], or using program instrumentation technique to extract these data in runtime [SHR⁺00]. Inspire by [SHR⁺00], and partially due to Java VM can only internally provide the data we want, our dynamic type recorder is implemented using instrumented technique.

6. Conclusion and future work

In this paper we have proposed Type Flow Analysis (TFA), an algorithm that statically determines reaching types of variable and constructs call graph edges for Object-Oriented programming languages. We have proved that our method is as precise as subset-based points-to analysis, regarding type related information. The computation of TFA is pure relational since it do not require a heap abstraction, which is needed by points-to analysis.

To evaluate our method in practice, we implement a static type analysis tool in Soot framework, which runs our algorithm. Moreover, a dynamic type profiler is used to extract run-time types of variables, which are then used to compare with static results. We implement it using instrumentation technique, abiding by specification of Java VM. We have compared our method with built-in CHA and points-to algorithms in Soot by experimental evaluation. The result have shown that our method achieved promising result. It is generally more practical in type resolution problem.

There are still some works we can do to enhance our algorithm. On theoretical aspect, we can develop our algorithm to context-sensitive, in a way similar to points-to analysis [MRR05, SBL11]. On practical aspect, we can combine static result and dynamic result to make our algorithm more adaptive, inspire by the approach proposed in [SWB⁺14].
